```

0.1 Quanto Model Review

Let X denotes the exchange rate measured in domestic currency for a unit of foreign currency:

$$\frac{dX}{X} = \mu_x dt + \sigma_x dB_x$$

Let S denotes the foreign asset measured in foreign currency:

$$\frac{dS}{S} = \mu_s dt + \sigma_s dB_s$$

where

- $(dB_x)(dB_s) = \rho dt$

- q - constant dividend yield of the foreign asset

- r - risk-free interest rate in domestic currency

- r_f - risk-free interest rate in foreign currency

A "**quanto**" is a derivative written on foreign asset an converted to domestic currency at a fixed exchange rate $\bar{X}$, i.e. $V(T) = \bar{X}S(T)$. The price of the quanto at time $t \le T$ is given by equation (6.7):

$$V(t) = e^{(r_f - r - q - \rho\sigma_x\sigma_s)(T-t)}\bar{X}S(t)$$

Following equation (6.14), a replication strategy for the quanto is given by:

- invest (long) $V(t)$ units of domestic currency in the foreign asset, which means buying $\frac{V(t)}{X(t)S(t)}$ shares of the foreign asset;

1

- borrow (short) $V(t)$ units of domestic currency at the foreign risk-free rate r_f;

- invest (long) $V(t)$ units of domestic currency in the domestic risk-free asset.

0.2 Question 6.5 Discretely-Rebalanced Quanto Hedge

Following the similar logic from "**Discretely-Rebalanced Delta Hedges**" (Section 3.10 in the textbook), the hedging strategy for the quanto can be implemented as follows:

1. At time $t_0 = 0$, the initial portfolio consists of:

   - long $V(0)$ units of domestic currency in the foreign asset, which means buying $\delta(0) = \frac{V(t_0)}{X(t_0)S(t_0)}$ shares of the foreign asset;

   - short $V(0)$ units of domestic currency at the foreign risk-free rate r_f;

   - long $V(0)$ units of domestic currency in the domestic risk-free asset, i.e., cash account $C(0) = V(0)$.

2. At each rebalancing time t_i, $i = 1, 2, \dots, N-1$, the portfolio is rebalanced to:

   - long $\delta(t_i) = \frac{V(t_i)}{X(t_i)S(t_i)}$ shares of the foreign asset;

   - short $V(t_i)$ units of domestic currency at the foreign risk-free rate r_f;

   - new cash account $C(t_i)$ includes:

     - adjusting shares of the foreign asset: $-(\delta(t_i) - \delta(t_{i-1}))S(t_i)X(t_i)$;

     - adjusting short position at the foreign risk-free asset: $V(t_i) - V(t_{i-1})e^{r_f \Delta t}X(t_i)/X(t_{i-1})$;

     - continuous dividend payment from the foreign asset: $\delta(t_{i-1})S(t_{i-1})(e^{q\Delta t} - 1)X(t_i)$;

     - accumulation/payment of interest on the cash position of domestic currency: $C(t_{i-1})e^{r\Delta t}$.

3. At date $t_N = T$, the value of the portfolio is:

   - foreign asset: $\delta(T-1)S(T)X(T)$;

   - dividend payment: $\delta(T-1)S(T-1)(e^{q\Delta t} - 1)X(T)$;

   - foreign risk-free asset: $-V(T-1)e^{r_f \Delta t}X(T)/X(T-1)$;

   - cash account: $C(T-1)e^{r\Delta t}$.

   - promised payment: $-\bar{X}S(T)$.

```python
def Quanto_Hedge_Profit(
    X0, mu_x, sigma_x, S0, mu_s, sigma_s, q, r, r_f, rho, X_bar, T, N

Distribution of Quanto Hedge Profits

0.3 Question 7.7 Discretely-Rebalanced Delta Hedges for Foward Call Option

As stated in Sect. 7.6 in the textbook, the delta-hedge portfolio for a written call option (option maturing at T, forward maturing at T', and $T < T'$) consists of:

- Long $F(0)N(d_1) - KN(d_2)$ units of the discounted bond maturing at T'

- Long $N(d_1)$ forward contracts.

This is a zero-cost portfolio when we include the proceeds from selling the call. Since forward contracts were worth zero at initiation, we don't need to adjust the bond position at each rebalancing time, because there is no other cash flow before the maturity.

The change of forward contracts position at each rebalancing time result in a cash flow of $x(t_{i-1})[F(t_i) - F(t_{i-1})]$ dollars to be received at forward maturity T' (see, Sect. 7.10 in the textbook), where $x(t)$ is the required hedge position of forward contract. So, the profit of the hedging strategy at option maturity T is:

$$\text{Profit} = P(T,T')\left[F(0)N(d_1) - KN(d_2)\right] + P(T,T')\sum_{i=1}^{N} x(t_{i-1})\left[F(t_i) - F(t_{i-1})\right] - P(T,T')\max(F(T) - K, 0)$$

```python
def Black_Call_Delta(F, K, sigma, T):
    d1 = (np.log(F / K) + 0.5 * sigma**2 * T) / (sigma * np.sqrt(T))
    d2 = d1 - sigma * np.sqrt(T)
    _F = norm.cdf(d1)
    _P = F * norm.cdf(d1) - K * norm.cdf(d2)
    return _F, _P

def Black_Call_Hedge_Profit(F0, K, mu, sigma, y, T, T_p, N):
    dt = T / N   # time step
    t = np.linspace(0, T, N + 1)   # time grid
    # Brownian motion B(t)
    B = np.zeros(N + 1)
```

```
        dB = np.sqrt(dt) * rng.standard_normal(size=N)
        B[1:] = np.cumsum(dB)
        # Forward price F(t)
        F = F0 * np.exp((mu - 0.5 * sigma**2) * t + sigma * B)
        # Discount bond price P(t, T')
        P = np.exp(-y * (T_p - t))
        # Positions of forward contract and discounted bond to hedge the call option
        _F, _P = Black_Call_Delta(F[:-1], K, sigma, T - t[:-1])
        # Cumulative cash flow at maturity T' from the change value of the forward␣
    ↪contracts
        dF = np.zeros(N + 1)
        for i in range(1, N + 1):
            dF[i] = dF[i - 1] + _F[i - 1] * (F[i] - F[i - 1])
        # portfolio value at option maturity T
